PUBLICATION OF THE SUPERIOR HEALTH COUNCIL No. 8651

Probiotics and their implications for Belgian public health

Microbiological characterization.

This project aims at taking stock of the methodologies that are suitable for validating the identity, the quality and the safety of probiotic flora (bacteria and yeast) as a food ingredient.

February 2012

FOREWORD

By engaging in this activity, the SHC’s ultimate objective has been to review the state of knowledge as regards the methodologies that make it possible to characterize strains and products with purported probiotic activity. This advisory report does not discuss specific strains, products or technologies.

In view of the rapidly expanding knowledge on this subject, the SHC finds it appropriate to issue a document that provides an overview of the practical tools that are currently available for validating the composition and innocuousness of these products.

This advisory report does not in any way confer approval on products purported to have probiotic activity as regards any clinical effectiveness they might have in preventing or treating pathologies ("health claim").

SUMMARY

When ingested in sufficient numbers, probiotics are expected to confer one or more proven health benefits on the consumer. As a food ingredient, they need to survive passing through the digestive tract and proliferate in the gut.

By embarking on this project, the Belgian Superior Health Council (SHC) hopes to provide healthcare professionals as well as the competent authorities with up-to-date information on the state of the art on the microbiological characterization of the live microorganisms concerned (authenticity and safety).

This document only concerns the characterization of probiotics. It provides up-to-date information on the state of the art on the microbiological characterization of the live organisms concerned (bacteria and yeasts). The examination of the health prospects linked to the use of probiotics (potential and development) as well as the recommendations to the competent authorities could be published at a later stage in the future.
In the present report:

1) This first part of the report on probiotics defines the characteristics of live microorganisms that can be looked upon as probiotics and describes phenotypic and molecular approaches for the correct identification of the strains and for a sufficiently precise taxonomical characterization. As regards typing, this document draws attention to the importance of constructing a database (detection, new species, etc.). A series of tables provides an overview of the information that has recently become available on this subject.

2) As regards assessing the safety of probiotics, avoiding the inclusion of pathogenic strains crucially relies on isolation and taxonomy. Recognising the health risks attendant to the use of probiotics presupposes that the strains used are properly identified. The focus is on the problems involved in standardizing the methods and interpreting the data. Verifying the (intrinsic or acquired) antibiotic resistance traits is of key importance in countering the spreading of antibiotic resistance. This document also describes a series of methodologies and means to interpret the data. The microorganisms concerned should display no virulence or pathogenic properties, which may induce clinical signs that can be very diverse, with more than the gastrointestinal region affected. Parameters such as adhesion, translocation, and colonization are still being heavily debated.

3) Finally, it is important to carry out an in-depth quality control for these “live” products by checking them against a set of parameters using the most appropriate methods. Indeed, probiotic biota can only be put to good use in the interest of public health if these conditions are met.

The examination of the health prospects linked to the use of probiotics (potential and development) as well as the recommendations to the competent authorities could be published at a later stage in the future.

Keywords
probiotics, typing, risk assessment, quality control, safety assessment.

MeSH terms
Probiotics; Bacterial typing techniques; Risk assessment; Consumer product safety.

ABBREVIATIONS AND SYMBOLS

ACE-ART: Assessment and Critical Evaluation of Antibiotic Resistance Transferability in Food Chain (EU project)
AFLP: amplified fragment length polymorphism
API: Analytical Profile Index tests
ARDRA: amplified ribosomal DNA restriction analysis
BSAC: British Society for Antimicrobial Therapy
BPW: buffered peptone water
CCFL: Codex Committee on Food Labeling (in Codex Alimentarius)
CCNFSDU: Codex Committee on Nutrition and Foods for Special Dietary Uses (in Codex Alimentarius)
CFU: colony-forming unit
CLSI: Clinical and Laboratory Standards Institute
DGGE: Denaturing Gradient Gel Electrophoresis
DNA: deoxyribonucleic acid
EFFCA: European Food and Feed Cultures Association
EFSA: European Food Safety Authority
EUCAST: European Committee on Antimicrobial Susceptibility Testing
EMBL: European Molecular Biology Laboratory
EHEC: enterohaemorrhagic E. coli
EIEC: enteroinvasive E. coli
EPEC: enteropathogenic E. coli
ETEC: enterotoxigenic E. coli
FAO: Food and Agriculture Organization
FISH: fluorescent in-situ hybridization
GG (L. rhamnosus GG): title of the strain derived from the names of Goldin and Gorbach
GRAS: generally recognized as safe
HBL: Haemolysin BL (from Bacillus cereus)
ICU: intensive care units
IDF: International Dairy Federation
ILSI: International Life Sciences Institute
ISO: International Organization for Standardization
ITS: internal transcribed spacer
LAB: lactic acid bacteria
LSM: LAB susceptibility test medium
LSU: large subunit
MIC: minimum inhibitory concentration
NDA: Panel on Dietetic Products, Nutrition and Allergies of the EFSA
NHE: non-hemolytic enterotoxin
NV: non-viable
NWT: non-wild-type (member of a species)
PCR: polymerase chain reaction
PROSAFE: Product Safety Enforcement Forum of Europe
QPS: qualified presumption of safety
RAPD: randomly amplified polymorphic DNA
RDP: Ribosomal Database Project
RFLP: restriction fragment length polymorphism
RNA: ribonucleic acid
PAI: pathogenicity island
SCAN: Scientific Committee on Animal Nutrition (EU)
SHC: Belgian Superior Health Council
SPF: specific pathogen free
ST: sequence type
STEC: Shiga-toxin-producing *E. coli*
VBNC: viable but non cultivable
VC: viable and cultivable
WHO: World Health Organization
WT: wild-type (member of a species)
1. INTRODUCTION

The word “probiotic” is relatively new and means “for life” (from the Greek προ βίος, pro bios). The works of Metchnikoff (1907) and Tissier (1906) were the first to make scientific suggestions concerning the probiotic use of bacteria, even if the word “probiotic” was not coined until 1960, to name substances produced by microorganisms which promoted the growth of other microorganisms (Lilly and Stillwell, 1965). Some other definitions followed, with Fuller (1989) being the first pointing out the microbial nature of probiotics by redefining the word “probiotic” as “a live microbial feed supplement which beneficially affects the host animal by improving its intestinal balance”. Havenaar and Huis in ‘t Veld (1992) extended the definition as “a viable mono- or mixed culture of bacteria which, when applied to animal or man, beneficially affects the host by improving the properties of the indigenous flora”. Guarner and Schaafsma (1998) gave a more recent definition as “live microorganisms, which when consumed in adequate amounts, confer a health effect on the host”.

According to the joint “Food and Agriculture Organization/World Health Organization (FAO/WHO) Expert Consultation on Evaluation of Health and Nutritional Properties of Probiotics in Food including Powder Milk with Live Lactic Acid Bacteria”, held from 1st to 4th of October 2001 in Córdoba (Argentina), probiotics were redefined for the purpose of the meeting as: “Live microorganisms which when administered in adequate amounts confer a health benefit on the host” (FAO/WHO, 2001). Following the FAO/WHO definition, the International Life Sciences Institute (ILSI, 2002) and the European Food and Feed Cultures Association (EFFCA, 2003) have launched similar definitions for a probiotic, namely “a live microbial food ingredient that, when taken up in adequate amounts, confers health benefits on the consumers” and “live microorganisms which, when ingested or locally applied in sufficient numbers, provide the consumer with one or more proven health benefits”, respectively.

The FAO/WHO expert consultation restricted its scope to the discussion of probiotics “as part of the food” and excluded reference to the term biotherapeutic agents and beneficial microorganisms not used in food. However, it is recognized that the definition is sufficiently broad as to encompass a range of probiotic preparations and intentions of use. In this respect, a probiotic can be a food or a dietary supplement, can be used in a drug application (also named a live biotherapeutic) or microbial feed or can be used as genetically modified microorganism or live vaccine if administered orally.

For use in food, important criteria for probiotics were documented, in particular that they should not only be capable of surviving passage through the digestive tract, by exhibiting acid and bile tolerance and withstand digestive enzymes, but also have the capability to proliferate in the gut. Probiotics must be able to exert their benefits on the host through growth and/or activity in the human body. Therefore, the ability to remain viable at the target site and to be effective should be verified for each strain.

In 2002 (London, Canada), a joint FAO/WHO working group generated Guidelines for the evaluation of Probiotics in Food (FAO/WHO, 2002). It was recommended to officially adopt the above FAO/WHO definition of probiotics and to use and adopt the guidelines in the report of this working group as a prerequisite to call a microbial strain “probiotic”. The minimum requirements needed for probiotic status include:
- the assessment of strain identity (genus, species, strain level);
- in vitro tests to screen potential probiotic strains: e.g. resistance to gastric acidity, bile acid and digestive enzymes, antimicrobial activity against potentially pathogenic bacteria, etc.;
- assessment of safety: requirements for proof that a probiotic strain is safe and without contamination in its delivery form;
- in vivo studies for substantiation of health effects in the target host.
The working group recommended that information accumulated to show that a strain is a probiotic, including clinical trial evidence, be published in peer-reviewed scientific or medical journals. Also, publication of negative results is encouraged, as to contribute to the totality of the evidence to support probiotic efficacy.

The recommendations of the above FAO/WHO Consultation and the Guidelines of the FAO/WHO working group have been assembled in one document (FAO/WHO, 2006) and were presented to two Codex Alimentarius Committees: the Codex Committee on Food Labeling (CCFL) and the Codex Committee on Nutrition and Foods for Special Dietary Uses (CCNFSDU). It is hoped that the work of the FAO/WHO probiotics groups will be used as a model for future Codex guidelines.

In relation to the substantiation of health effects of probiotics in the target host, it is important to know that in the European Union, health claims should only be authorized for use in the Union after a scientific assessment of the highest possible standard has been carried out by the Panel on Dietetic Products, Nutrition and Allergies (NDA) of the European Food Safety Authority (EFSA) [Regulation (EC) No. 1924/2006]. Key questions which are addressed by the EFSA NDA panel are:
- is the food/constituent sufficiently defined and characterized?
- is the claimed effect sufficiently defined, and is it a beneficial physiological effect?
- have pertinent human studies been presented to substantiate the claim?

If the outcome of all of the above questions is favourable, the panel weighs the evidence from all the pertinent studies presented, including human, animal, in vitro and mechanistic studies.

The NDA panel has provided general guidelines on how health claims related to gut and immune function are scientifically evaluated (EFSA NDA 2011); these guidelines are particularly interesting for probiotics which are usually expected to have this kind of health effects. The guidelines are not intended as an exhaustive list of beneficial effects and acceptable studies/outcome measures, but rather present examples drawn from evaluations already carried out to illustrate the approach of the panel.

Finally, it should be emphasized that besides strain identification and characterization, survival of the passage of the upper gastrointestinal tract, transient adhesion to or interaction with the intestinal epithelium and colonization of the colon and resistance of the strains towards technological processing and storage is of utmost importance. This underlines the importance of the food matrix and the applied process technology to prepare the food (constituent) and the requirement for stability and survival of the strain until the moment of consumption of the food. This in turn points toward food matrix dependency (including amount of food to be consumed for a proven health effect) and the importance of an adequate amount of live active cells, respectively.

In view of the rapidly expanding knowledge on this subject, this first part of the report on the issue of probiotics provides up-to-date information on the state of the art on the microbiological characterization of the live microorganisms concerned (bacteria and yeasts).

The examination of the health prospects linked to the use of probiotics (potential and development) as well as the recommendations to the competent authorities will be published at a later stage (part 2).
2. STRAIN IDENTIFICATION AND TYPING

2.1. Microbial species used as probiotics for human application

A wide range of product types containing viable or heat-killed microorganisms with probiotic claims are commercially available either as fermented food commodities, foods with probiotic ingredients, or in lyophilised form. In accordance to the widely used FAO/WHO definition of probiotics (FAO/WHO, 2001), this chapter will only deal with the identification and typing of live microorganisms used as probiotics for human applications.

With the emphasis mainly on fermented dairy products, a steadily increasing range of yogurt-like products is available on the European market. Probiotic strains used in these products are generally, but not exclusively, derived from the gastrointestinal tract of presumed healthy humans. This is reflected by the high frequency in which strains of autochthonous *Lactobacillus* and *Bifidobacterium* species are applied in these products (Holzapfel *et al.*, 1998; 2001; Klein *et al.*, 1998; Sanders *et al.*, 2003; Table 1). *Lactobacillus* is a member of the lactic acid bacteria (LAB) and is naturally occurring on raw food and feed materials but is also a member of the intestinal tract of most mammals. Although also a lactic acid producing bacterium, *Bifidobacterium* is not considered a typical member of the LAB, due to its remote phylogenetic position. To a lesser extent, also other LAB strains belonging to genera such as *Enterococcus*, *Lactococcus* and *Pediococcus* are used as probiotics for humans mainly in dairy-based products. In contrast, strains of non-LAB bacteria such as *Bacillus*, *Propionibacterium* and *Escherichia coli* used as probiotic are rarely included in dairy or other food commodities, but are usually applied as lyophilised or encapsulated pharmaceutical preparations. The use of yeasts in commercial probiotic products is virtually restricted to a single strain commonly referred to as *Saccharomyces cerevisiae* var. boulardii (Czerucka *et al.*, 2007), although also other non-pathogenic yeast strains have been the subject of probiotic studies (Foligné *et al.*, 2010).

Importantly, not all microorganisms present in a probiotic product per definition have probiotic characteristics. A typical example is the case of strains of the yogurt starters *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus*, which are applied mainly for technical reasons but are not commonly regarded as probiotics. The latter point is still under debate as literature searches have shown that viable yogurt starter cultures have the potential to improve lactose digestion and eliminate symptoms of lactose intolerance (Guarner *et al.*, 2005).

The relevance of reliable identification and typing of strains used in probiotic applications is still increasing because of two main reasons. Firstly, it is clear that the use of probiotic strains is no longer strictly restricted to food applications where history of safe use in (traditional) fermented foods was an important argument to neglect the importance of correct classification of probiotics. In recent years, however, probiotics are also more and more used in biotherapeutic and pharmaceutical applications, which are aimed at specific patient groups each with their own clinical risk profiles. As a part of the biosafety evaluation in the course of this type of clinical interventions, it is now commonly accepted that correct identification to the species level and even to the strain level is essential. Secondly, probiotic use no longer only involves monocultures but has meanwhile also witnessed the introduction of several mixed-strain formulations in food products with health-promoting claims as well as in therapeutic trials and applications. As part of any health claim dossier, it is clear that the individual strains composing such mixtures need to be fully characterized taxonomically.
2.2. Identification

At present, the inappropriate use of identification methods is regarded as the major cause of incorrect species designations of probiotic strains (Huys et al., 2006) and mislabelling of probiotic products (Duc et al., 2004; Masco et al., 2005; Temmerman et al., 2003). Inconsistencies in the microbial identification of commercial products with probiotic claims affects their potential efficacy and safety record, and are likely to have a negative impact on consumer trust.

2.2.1 Phenotypic approaches for bacterial identification

For identification of probiotic bacterial strains, phenotypic tests or commercial miniaturized identification systems such as Analytical Profile Index tests (API) are inadequate for species level resolution. In fact, it is recommended that biochemical characterization should not be used as a stand-alone approach for identification of any probiotic culture. Commercial identification systems may be useful to obtain a first tentative classification at the genus level in conjunction with primary phenotypic tests, but the identification result should in any case be confirmed by other (molecular) methods. It is important to highlight that the usefulness of (commercial) biochemical systems for identification of probiotic bacterial strains is limited, due to the high intra-specific phenotypic variability observed in many bacterial species, and due to the fact that updates of the identification databases linked to these systems are slow or even missing, are often incomplete, and that species entries are poorly documented without listing the reference strains used (Vankerckhoven et al., 2008).

2.2.2 Molecular approaches for bacterial identification

Despite the event of sequence-based approaches, DNA-DNA reassociation is currently considered as the “gold standard” for delineation and description of new bacterial species, but is impractical in routine identification of bacterial cultures. Other molecular methods are therefore preferred provided that they offer sufficient experimental reproducibility and a proper taxonomic resolution and that they make use of updated and easily available and validated identification databases. The use of molecular approaches for identification of species used in probiotic applications is covered in large detail in several review articles (Holzapfel et al., 1998, 2001; Ward & Roy, 2005).

Sequence analysis of the partial or complete 16S ribosomal ribonucleic acid (rRNA) gene is now commonplace as the first tool to use for the taxonomic positioning of probiotic cultures (Yeung et al., 2002). Next to the universal distribution of this gene in all bacterial species, which avoids the use of group-specific protocols, other obvious advantages of using this and other sequence-based methods include the high-level of data reproducibility and exchangeability. Sequencing is now commonly outsourced to specialised service providers and sequencing centers, often with satisfactory to excellent results. The major bottleneck of the 16S rRNA gene sequencing approach for non-experienced users, however, is the taxonomic interpretation of the sequence data by comparison with public sequence databases such as European Molecular Biology Laboratory (EMBL http://www.ebi.ac.uk/emb/) and GenBank (http://www.ncbi.nlm.nih.gov/genbank/). These databases often contain loads of unreliable, poorly documented, or incomplete sequence entries, which may compromise the accuracy of the identification result. Therefore, experienced users will have to make sure that only validated and complete 16S rRNA gene sequences are used for identification purposes and that full 16S rRNA gene sequences of multiple taxonomic reference strains per taxon (certainly including the type strain) are included in the identification database to encompass the genomic variation within the taxon. The Ribosomal Database Project (RDP; http://rdp.cme.msu.edu/) and the Silva rRNA database project (http://www.arb-silva.de/) are two free web-based applications that provide ribosome-related data and services to the scientific community, including online data analysis and aligned and annotated 16S rRNA gene sequences.
In addition to their use for straightforward identification of pure cultures, ribosomal sequences have also been exploited for culture-independent detection of probiotic microorganisms. The use of rRNA-targeted probes provides a unique insight into the dynamics of probiotic microorganisms in complex microbial communities. Nucleic acid probes have been designed to specifically target taxonomic groups at different levels of specificity (from genus to strain). The review by Ben Amor and co-workers (2007) presents a good overview of the currently available and validated 16S rRNA-targeted oligonucleotide probes for the identification of LAB ranging from group and genus to species and subspecies level.

Despite its obvious advantages, it has been shown that 16S rDNA sequencing has a limited resolution for the discrimination of very closely related species, including those which are frequently used in probiotic foods and preparations. Within the genus *Lactobacillus*, for example, some species of the *Lactobacillus delbrueckii* group, the *Lactobacillus casei* group, and the *Lactobacillus plantarum* group are difficult to separate even when using full 16S rRNA gene sequences (Klein et al., 1998; Torriani et al., 2001). In the case the probiotic strain belongs to one of these species, results of 16S rRNA gene sequence identification may only be reliable at the genus level and need to be complemented by other molecular methods to obtain classification at (sub)species level (Huys et al., 2006). To this end, a series of fingerprinting methods including repetitive DNA element (rep)-PCR (polymerase chain reaction), amplified fragment length polymorphism (AFLP), amplified ribosomal DNA restriction analysis (ARDRA) and tDNA intergenic spacer PCR (tDNA-PCR) have been evaluated and optimized for species identification of most probiotic microorganisms (Table 2). In contrast to sequence-based approaches, however, fingerprint data are much less exchangeable and reproducible between laboratories and strongly rely on the availability of an extended and up-to-date database of reference profiles. For this reason, fingerprint-based identifications are best performed in expert labs that use standardized protocols and have access to in-house databases for identification of unknown cultures.

The use of protein-encoding housekeeping genes essentially combines the technological advantages of 16S rRNA gene sequencing and the taxonomic resolution of many fingerprinting methods. Sequencing of one or preferably multiple of these genes as taxonomic markers is a crucial step forward in the development of standardised and globally accessible methods for the identification of probiotic cultures. For LAB, the combined sequence analysis of the *atpA*, *pheS* and *rpoA* genes has been successfully explored for species identification of enterococci (Naser et al., 2005), lactobacilli (Naser et al., 2007), leuconostocs (De Bruyne et al., 2007) and pediococci (De Bruyne et al., 2008). Analysis of partial *hsp60* (Zhu et al., 2003) and *rpoB* (Kim et al., 2010) gene sequences have proven to be useful single-locus approaches for the differentiation of *Bifidobacterium* spp. However, concatenation of partial sequences of seven genes (*clpC*, *dnaB*, *dnaG*, *dnaJ*, *purF*, *rpoC* and *xfp*) may significantly increase the discriminatory power between bifidobacterial species (Ventura et al., 2006). Within the *Bacillus subtilis* group and related taxa, the use of housekeeping genes *gyrB* (Wang et al., 2007) and *rpoB* (Palmisano et al., 2001) is often used for reliable species differentiation.

The most recent insights from whole-genome sequencing have indicated that even conserved genes such as protein-encoding housekeeping genes may be subjected to genomic rearrangements such as deletions, duplications, mutations, recombinations, and lateral gene transfer. This important finding thus suggests that the classification of microorganisms may not be accurately reflected by analyzing the sequences of one gene or a cluster of genes. The current availability of complete genome sequences of thousands of bacterial strains allows to investigate new avenues for bacterial phylogeny and identification. Within the LAB and *Bifidobacterium* species used as probiotics for human applications, the complete genome sequences of more than 50 strains have been submitted to GenBank (Table 3). To compare whole-genome sequences for taxonomic purposes, the possibilities of supertree construction are currently being exploited. In this approach, the information from hundreds of individual phylogenetic trees, each encompassing a set of orthologous gene families are assembled in one single supertree.
Although the advanced bioinformatics tools required for this type of analyses are still being developed and/or under evaluation, it is expected that extraction of taxonomic data from whole genomes will eventually also find its place in the identification of probiotic microorganisms such as LAB.

### 2.2.3 Yeast identification

Identification and classification of yeasts have traditionally been based on morphological, physiological, and biochemical traits. Various commercial biochemical kits have been developed for rapid yeast identification, but mostly for the clinical market. Currently, different molecular biology techniques are available for identification of yeasts.

A reliable starting point for the identification of probiotic yeasts is the D1/D2 large subunit (LSU) rRNA gene sequence database, which encompasses virtually all known yeast species (Fell et al., 2000). However, due to the fact that some distinct species show low sequence divergence, the use of D1/D2 LSU sequences is often complemented by PCR amplification of repetitive DNA elements (Lieckfeldt et al., 1993) and by determination of additional gene sequences, such as the internal transcribed spacer (ITS) region of the rRNA gene cluster (Scorzetti et al., 2002) or protein-coding genes such as the actin gene (ACT1; Daniel & Meyer, 2003), and the mitochondrial cytochrome oxidase 2 (COX2) and cobalamin-independent methionine synthase (MET6) genes (Gonzáles et al., 2006).

### 2.3. Typing

#### 2.3.1 Bacteria

In many cases, it is of high importance to characterize probiotic cultures at the individual strain level, a process generally referred to as typing. Such cases may include screening large microbiological collections for probiotic candidates, monitoring selected candidate strains during in vitro and in vivo trials, quality control of probiotic products, strain authentication in legal matters and epidemiological surveys.

To a large extent, typing of probiotic microorganisms still relies on the use of molecular methods (Holzapfel et al., 2001). Several fingerprinting methods that have been used for species identification such as (rep)-PCR and AFLP are also suitable as typing methods up to the strain level (Table 2). Especially in the case of AFLP, the flexibility in choice of specific restriction enzymes and selective PCR primers allows to test multiple combinations, which can significantly increase the discriminatory power at strain level. Depending on the number of isolates to be processed, the required speed of performance, and the expertise of the user, also randomly amplified polymorphic DNA (RAPD) and pulsed-field gel electrophoresis (PFGE) can be applied for typing of probiotic strains (Table 2). RAPD allows fast and reliable comparison of larger sets of isolates in a single PCR run, but often lacks the same level of reproducibility offered by other PCR-based fingerprinting techniques, which is an important prerequisite for database construction. Nevertheless, RAPD is still frequently used to discriminate between probiotic strains (Manan et al., 2009; Ratna Sudha et al., 2010). Together with AFLP, by far the highest resolution at strain level can be achieved by PFGE. Although the latter method can be standardized, it requires a dedicated electrophoretic unit and considerable technical expertise. PFGE fingerprinting has been successfully used to differentiate or track probiotic strains in the genera *Bifidobacterium* (Roy et al., 1996; Grand et al., 2003; Masco et al., 2005), *Lactobacillus* (Coudeyras et al., 2008; Vancanneyt et al., 2006; Wind et al., 2010), and *Bacillus* (De Baets et al., 2009).

In addition to DNA fingerprinting, also sequence-based approaches have been used to discriminate or detect individual probiotic strains. The availability of complete genome sequences of probiotic strains not only broadens our biological knowledge of their functional potential, but
also offers a myriad of new possibilities for strain differentiation. Based on internal nucleotide sequences of multiple (usually three to seven) housekeeping genes, several multilocus sequence typing (MLST) schemes have been developed for discrimination between bacterial isolates at the intraspecific level. For each gene, 450-500 bp internal fragments with a maximal number of polymorphisms are selected for amplification and subsequent gene sequence analysis. For each housekeeping gene, the different sequences present within a bacterial species are assigned as distinct alleles and, for each isolate, the alleles at each of the loci define the allelic profile or sequence type (ST). The MLST method has several advantages, including reproducibility and data exchangeability and can be automated to a large extent. While MLST is primarily used to study population structure, evolution and phylogeography of bacterial pathogens (Achtman, 2008), depending on the species it also provides good discriminatory power to differentiate isolates for typing purposes. For bacteria, MLST schemes were first developed for clinically relevant microorganisms such as Enterococcus faecium (Homan et al., 2002; http://efaecium.mlst.net) and Bacillus cereus (Helgason et al., 2004; http://pubmlst.org/bcereus/).

In recent years, MLST schemes have also been developed for several other species commonly applied as probiotics. MLST schemes relevant for typing of probiotic lactobacilli include those developed for the species Lb. casei (Cai et al., 2007; Diancourt et al., 2007), Lb. plantarum (de las Rivas et al., 2006), and Lb. salivarius (Raftis et al., 2011). Recently, an MLST scheme was made available for the probiotic Bifidobacterium species Bf. animalis, Bf. bifidum, Bf. breve, and Bf. longum (Delétoile et al., 2010). Similar to the mlst.net database for bacterial pathogens, MLST sequence type databases have been launched, for example, for Lb. casei (http://www.pasteur.fr/recherche/genopole/PF8/mlst/Lcasei.html) and Bifidobacterium (http://www.pasteur.fr/recherche/genopole/PF8/mlst/Bifidobacterium.html). These public databases allow queries and downloads of allele sequences and allelic STs, provide several database tools and statistics and are also open to additional data on novel strains and species.

In addition to MLST approaches, analysis of whole genome sequences through comparative genomics can be very useful to identify unique gene sequences that allow to discriminate a given probiotic culture from other members of the same species. Such strain-specific target sequences can then be used to detect a given probiotic in complex environments, such as food matrices or fecal samples, without the need for culturing. Instead, culture-independent methods such as fluorescent in-situ hybridization (FISH) and real-time PCR are employed for direct detection and enumeration of the target strain in the sample.

### 2.3.2 Yeasts

Typing of probiotic yeasts has largely been based on intraspecies polymorphisms located in the ITS regions of the ribosomal gene cluster. As an alternative to ITS sequencing, restriction fragment length polymorphism (RFLP) analysis of amplified ITS regions has been used to differentiate Saccharomyces yeasts isolated from various commercial probiotic and biotherapeutic products claimed to contain S. cerevisiae or S. boulardii (Mitterdorfer et al., 2002). In the latter study, the ITS-based approach was combined with RAPD and PFGE fingerprinting to differentiate Saccharomyces cerevisiae var. boulardii strains from other strains in the species. Previously, Baleiras Couto et al. (1996) had already suggested that discrimination of individual strains within S. cerevisiae is not possible with a single typing technique. In a comparative study with ITS-based approaches, microsatellite DNA polymorphism analysis and retrotransposon Ty917 hybridization analysis were considered to offer the highest discriminatory power to distinguish probiotic and clinical S. cerevisiae var. boulardii isolates from other clinical S. cerevisiae isolates (Posteraro et al., 2005). More recent developments in typing of S. cerevisiae strains focus on the design of MLST schemes. So far, the MLST approach has mainly been applied in wine yeast typing but does not seem to offer the same level of resolution as microsatellite analysis (Muñoz et al., 2009).

Cons.

Considering their importance in yogurt production, strains of *Lb. delbrueckii* subsp. *bulgaricus* and *S. thermophilus* were also included in the table.

The species name as mentioned in the Complete Microbial Genomes list of NCBI (http://www.ncbi.nlm.nih.gov/genomes/lproks.cgi) is not necessarily in accordance to the current bacterial nomenclature.

The Reference Sequence (RefSeq) database of NCBI provides a comprehensive standard dataset that represents sequence information for a species. RefSeq sequences are derived from GenBank records but differ in that each RefSeq is a synthesis of information, not an archived unit of primary research data.

Strains used as probiotics.
3. SAFETY ASSESSMENT OF PROBIOTICS

3.1. Introduction

In general, the microorganisms used in the production of food fermentation have a long history of safe use and are often referred to as “food grade” or GRAS (Generally Recognized As Safe) microorganisms (Holzapfel et al., 1998). Hence, this is the case for most LAB and bifidobacteria (Leroy & De Vuyst, 2004; Foulquié Moreno et al., 2006; Wessels et al., 2004). In Europe, the Qualified Presumption of Safety (QPS) concept exists with a list of microorganisms that can be considered safe for use. The microorganisms intended for human use are regulated in the EU in the context of novel food regulation (Regulation (EC) N°258/97; http://ec.europa.eu/food/food/biotechnology/novelfood/index_en.htm). For microorganisms (probiotics) used as additives in animal feed (Regulation (EC) N°1831/2003), official guidelines for their safety assessment have been fixed at EU level by Regulation (EC) N°429/2008.

In recognition of the importance of assuring their safety for human purposes, even among LAB which are generally considered to have a very good safety record, new and existing probiotic strains need to be characterized with respect to a number of safety aspects. Epidemiological surveillance studies are very important to evaluate the risk of probiotics used in a specific population. In general, four types of side effects of probiotics can be distinguished: systemic infections, metabolic and enzymatic effects, immunomodulation and adjuvants and gene transfer. Among these, the most direct safety risk associated with the consumption of microorganisms is infection (e.g. endocarditis), especially in immunocompromised individuals. In general, the risk of infection by probiotic Lactobacillus or Bifidobacterium strains is similar to the risk of infection by commensal strains, and thus products containing such probiotic strains present a negligible risk to consumers (Ouwehand & Vesterlund, 2003). On the other hand, some strains of other LAB groups such as enterococci are agents of opportunistic infections. Rare cases of infection associated with certain Lactobacillus strains have been reported, mostly in immunocompromised patients (Cannon et al. 2005). Bifidobacteria are extremely rarely associated with infections (Hata et al., 1988). Bifidobacterium-associated infections are most likely caused by bifidobacteria from the patients’ own microbiota (Wang et al., 1996; MacFie et al., 1999). A recent study reported that the administration of the probiotic E. coli strain Nissle 1917 to immunocompromised patients may lead to severe adverse effects (Gronbach et al., 2010).

To establish safety guidelines for probiotic microorganisms, a FAO/WHO working group recommended that probiotic strains are characterized by a series of tests including antibiotic resistance, metabolic activities, toxin production, haemolytic activities, infectivity in immunocompromised animal models, side effects in humans, and adverse outcomes in consumers (FAO/WHO, 2002).

Although still under debate, it is generally agreed that probiotic safety aspects should cover the isolation history and species identity of the probiotic culture and provide phenotypic and/or genotypic evidence showing that the culture does not harbour acquired antibiotic resistance traits, putative virulence factors or other pathogenic properties (Sanders et al., 2010; Salminen et al., 1998; Vankerckhoven et al., 2008b). In addition, it has been suggested that translocation, adhesion and colonization may also contribute to the safety dossier of a probiotic strain. However, current problems in method standardization and data interpretation may need to be solved first before the usefulness of these parameters can be truly accepted.
3.2. Isolation history and taxonomic characterization

Although still a matter of debate, it has been suggested that probiotic strains should originate from the species of intended use. One can argue that a probiotic strain originating from the gastrointestinal tract of a healthy human can function better in a similar environment from where it was originally isolated. Although this point of view has been supported by the fact that most current successful strains are indeed of human origin, some animal-derived strains have also shown positive effects on humans.

In addition to documenting its strain history, the first step in (a) microorganism(s) or product being referred to as a probiotic is to identify the microorganism using internationally accepted methodologies, preferably by combining phenotypic and genotypic methods. The practical approaches for accurate determination of species identity of probiotic cultures have been discussed extensively in Chapter 2. Correct identification at species level also implies the use of scientifically recognized names and adequate designation of particular strains. The current state of evidence suggests that different strains can possess different features related to different safety risks, implying that it is not possible to identify the specific safety risks associated with a probiotic strain without proper identification. Reliable identification is also necessary to avoid the inclusion of pathogenic microorganisms in probiotic products.

3.3. Antimicrobial resistance

Due to the indiscriminate use of antibiotics in human and veterinary medicine and as animal growth promoters, antibiotic resistance has become an increasingly common characteristic in (food-borne) microorganisms (Threlfall et al., 2000), causing serious problems in treatment of microbial infections. Antibiotic resistance in bacteria may be intrinsic or acquired. Intrinsic resistance is a naturally occurring trait that may be characteristic for a given species or genus, whereas acquired resistance derives either from genetic mutations or acquisition of foreign DNA from other bacteria.

Probiotic strains with non-transmissible antibiotic resistances do not usually confer a safety concern. To some extent, non-transmissible antibiotic resistance might even be a useful property, if the probiotic strain is to be used as a prophylactic agent in the treatment of antibiotic-associated diarrhoea (Charteris et al., 1998a,b).

However, antibiotic resistance linked to transferable plasmids and mobile elements is a different case because of the possibility of resistance spreading to other, potentially more harmful bacteria. In the end, such increases in the dissemination of antibiotic resistance genes can drastically reduce the therapeutic possibilities in infectious diseases. Given the documented presence of antibiotic resistance genes in LAB and the indirect evidence that these genes could be transferred along the food chain (Teuber et al. 1999; Gevers et al., 2003; Jacobsen et al., 2007), it is therefore relevant to assess the presence of transferable antibiotic resistances in LAB strains that are or shall be used as probiotics for human consumption, an opinion which is adopted by EFSA (2005). Different expert panels have indicated that strains harbouring transferable antibiotic resistance genes are not suitable for use as probiotics (Salminen et al., 2001; Vankerckhoven et al., 2008). In this context, the specific risks related to each probiotic strain must be carefully identified.

For phenotypic antimicrobial susceptibility testing of bacterial species with clinical relevance such as enterococci, enterobacteria and certain Bacillus species, expert committees such as those appointed by the Clinical and Laboratory Standards Institute (CLSI; www.clsi.org/) and the British Society for Antimicrobial Therapy (BSAC; www.bsac.org.uk/) have proposed a series of standardized and harmonized methods that can be easily performed in most routine labs. However, for non-enterococcal LAB and bifidobacteria, which together account for the vast majority of probiotic cultures currently used, no such standards are available from CLSI, BSAC or
other committees. As a result, a variety of non-congruent methods and protocols for the determination of antibiotic susceptibilities of non-enterococcal LAB have been reported in the literature using agar (overlay) disc diffusion, E-test, broth dilution, and agar dilution (Klare et al., 2005). In general, dilution methods and E-test are preferred as reference methods over conventional diffusion-based tests, as the former techniques allow determining minimal inhibitory concentration (MIC) values which provide a more reliable indication of the intrinsic or acquired nature of a given resistance phenotype. However, due to the fact that many non-enterococcal LAB require specific growth conditions in terms of medium acidity and carbohydrate supplementation, conventional media such as Mueller-Hinton (as recommended by CLSI) and Iso-Sensitest agar (as recommended by BSAC) are not suitable for susceptibility testing of probiotic lactobacilli, pediococci, lactococci, and bifidobacteria. In the course of the EU project PROSAFE, two new test medium formulations have been developed for antimicrobial susceptibility testing of non-enterococcal LAB (Klare et al., 2005). The resulting LAB Susceptibility test Medium (LSM) consists of a mixture of Iso-Sensitest broth (90%, v/v) and de Man-Rogosa-Sharpe (MRS) broth (10%, v/v), supplemented with 0.3 g/L L-cysteine hydrochloride for bifidobacteria. The use of the LSM formulation has further been substantiated in another EU project, ACE-ART (www.aceart.net), which resulted in the proposal to use this medium as standard medium for susceptibility testing of lactobacilli and bifidobacteria from food and non-food origin. Recently, the intra- and interlaboratory performance of the LSM medium and related formulations, specifically adapted for MIC testing of bifidobacteria, Streptococcus thermophiles and Lactococcus lactis, has been positively evaluated in a small-scale harmonization study (Huys et al., 2010). In parallel, a standard operating procedure, based on data from the PROSAFE and ACE-ART projects, has been validated as an official shared standard of ISO/IDF (International Dairy Federation), i.e. ISO 10932:2010 (IDF 223:2010) standard “Milk and Milk Products - Determination of the Minimal Inhibitory Concentration (MIC) of Antibiotics Applicable to Bifidobacteria and Non-Enterococcal Lactic Acid Bacteria (LAB)” (www.iso.org/iso/iso_catalogue/catalogue_tc/catalogue_detail.htm?csnumber=46434).

The interpretation of MIC data in order to decide whether a (potential) probiotic strain harbours an acquired or atypical antibiotic resistance trait highly depends on the availability of epidemiological cut-off values. The European Committee on Antimicrobial Susceptibility Testing (EUCAST; www.eucast.org) has proposed a number of definitions towards a uniform MIC interpretation. A microorganism is either defined as a wild-type (WT) or non-wild-type (NWT) member of a species by the absence or presence, respectively, of acquired and mutational resistance mechanisms to the antimicrobial agent in question. The strain in question is categorised as WT or NWT within a species based on the cut-off values appropriate for that species and determined with a defined phenotypic test system. This cut-off value will not be altered by changing circumstances and WT microorganisms may or may not respond clinically to antimicrobial treatment (www.srga.org/eucastwt/eucastdefinitions.htm). Ideally, cut-off values are defined at the species level, not at the genus level. In this respect, the availability of correct species identification is an important prerequisite to define such species-specific cut-off levels. For a range of Lactobacillus species or species groups, including Lb. delbrueckii group, Lb. plantarum, Lb. sakei, Lb. rhamnosus, Lb. paracasei group, Lb. reuteri and Lb. fermentum, specific MIC distributions and tentative cut-off values for a range of antibiotics have been summarized by Korhonen and co-workers (2008). Importantly, these data were obtained using a standard protocol that is largely compatible with the experimental procedures outlined in ISO 10932:2010 (IDF 223:2010). Likewise, MIC distribution data for several important bifidobacterial taxa, including Bif. adolescentis group, Bf. longum group, Bf. bifidum, Bf. catenulatum group and Bf. Animalis, have been published (Mättö et al., 2007).

Probiotic cultures belonging to the NWT population of a species and thus in which phenotypic resistance has been detected may have acquired antibiotic resistance genes located on plasmids or (conjugative) transposons that may be further transmitted to other microorganisms. The other possibility, i.e. that the antibiotic resistance is due to mutations of chromosomal housekeeping genes, represents a negligible risk of horizontal dissemination. Verification of the presence of
antibiotic resistance genes is thus crucial and can be achieved by the use of dedicated PCR assays when a very specific resistance trait is targeted. The majority of acquired resistance genes so far found in (probiotic) LAB and bifidobacteria are those conferring resistance to tetracycline (i.e. \textit{tet} genes) and erythromycin (i.e. \textit{erm} genes). PCR primers specific for \textit{tet} and \textit{erm} genes are published and have been validated for use in \textit{Lactobacillus} and \textit{Bifidobacterium} (Kläre \textit{et al.}, 2007; Masco \textit{et al.}, 2006). In the case that the potential presence of multiple, rare, or silent (i.e. not phenotypically detectable) resistance genes needs to be verified, the use of dedicated microarrays (Kastner \textit{et al.}, 2006; van Hoek \textit{et al.}, 2008) can be recommended.

If the presence of one or multiple resistance genes is verified, the next step in the risk safety assessment could be to check transfer of the gene(s) under experimental conditions (Gevers \textit{et al.}, 2003; Huys \textit{et al.}, 2006). However, failure to demonstrate \textit{in vitro} horizontal gene transfer does not exclude the risk of dissemination of genes. Thus, whilst negative transfer experiments do not provide evidence for the absence of transfer, standardised transfer methods are still required to estimate whether the probability for resistance transfer is low or high. A standardized conjugation protocol has been developed and validated by several laboratories to assess antibiotic resistance transfer between lactococcal species (Lampkowska \textit{et al.}, 2008). However, such protocols still need to be established for \textit{in vitro} transfer experiments with lactobacilli and bifidobacteria.

### 3.4. Virulence/pathogenic properties

In general, potential probiotic strains should be screened \textit{in vitro} for their interactions with cell lines to investigate possible cytotoxic or cytopathological effects after growth in different media, for the presence of known virulence genes (e.g. lecithinase activity, toxin genes) and for the presence of mobile genetic elements. After these \textit{in vitro} tests for potentially safe use, \textit{in vivo} toxicity tests and persistence studies would be required. A recent study by Hütt \textit{et al.} (2011) shows how to evaluate the \textit{in vivo} safety and persistence of \textit{Lactobacillus} strains in the gastrointestinal tract of healthy adult volunteers after oral consumption of high doses of lactobacilli.

The long history of safe use of probiotic LAB is the best evidence for the safety of probiotic products. \textit{Lactococcus} and \textit{Lactobacillus} are most commonly given the “generally recognized as safe” or GRAS status. Other LAB genera like \textit{Streptococcus} and \textit{Enterococcus} and other genera that could be used as probiotics contain opportunistic pathogens (Gueimonde \textit{et al.}, 2004). The absence of pathogenicity of any potential probiotic strain must be shown to prove its safety.

It should be addressed that in general the number of infections with \textit{Lactobacillus} strains are very low. For instance, the risk of \textit{Lactobacillus} infections is estimated at about one case per 10 million people over a century of probiotic consumption in France (Bernardeau \textit{et al.}, 2006). Even after performing different clinical trials and human studies, including one involving enteral feeding of premature infants with a commercial \textit{Lactobacillus rhamnosus} strain called GG, no pathogenic potential could be indicated (Saxelin, 1997). However, a recent review by Cannon \textit{et al.} (2005) reported all cases of lactobacillemia identified through a Medline search of articles published between 1950 and 2003. From the 241 cases identified, lactobacilli were implicated in endocarditis, bacteremia and localized and other infections. \textit{Lactobacillus casei} and \textit{Lb. rhamnosus} (amongst which a case due to consumption of large quantities of fermented milk with the probiotic strain GG in the months before hospitalisation; Rautio \textit{et al.}, 1999) were the species most commonly responsible for these pathologies. In recent years, some cases of liver and spleen abscesses caused by lactobacilli have been described (Cukovic-Cavka \textit{et al.}, 2006; Chan \textit{et al.}, 2010; Doi \textit{et al.}, 2011). Most of these lactobacillemia cases are associated within the population with a reduced immune function. In a recent comprehensive review on probiotic infections in patients receiving probiotics in conjunction with nutritional support, it appeared that all 20 case reports of adverse events in 32 patients involved infections due to \textit{Lb. rhamnosus} GG.
or Saccharomyces boulardii, the risk factors included central venous catheters and disorders associated with increased bacterial translocation (Whelan and Myers, 2010). The dominance of these two probiotic species in these reported cases may be linked to their wider use in clinical settings rather than their increased virulence. The question if food containing probiotics is at the origin of the endocarditis cases is not clear because Lactobacillus isolates from blood cultures and from commercially dairy products are different based on the carbohydrate fermentation (Saxelin et al., 1996). Another report described the case of a person suffering of a Lactobacillus associated endocarditis after having teeth extracted due to caries. The non-gastrointestinal way of consumption is maybe at the origin of this infection (Mackay et al., 1999). But in general, it could be said that the frequency of Lactobacillus infective endocarditis is very low, between 0.05 and 0.4% of the total of bacterial endocarditis cases. The results should be handled with care due to false or incomplete identification of the strains in some studies, which highlighted the necessity of molecular tools for strain identification (Lau et al., 2004).

In contrast to Lactobacillus spp. the genus Enterococcus has a higher potential safety risk, although enterococci are used as starter cultures in the food industry as well as probiotics (Foulquie Moreno et al., 2006; Franz et al., 2011). It is emerging as a major cause of nosocomial infection causing endocarditis, bacteremia, central nervous system infections, neonatal infections, urinary tract infections and other infections, and isolates are increasingly found to carry virulence factors (Choi et al., 2004). The origin of enterococcal pathogenicity is linked to factors involved in adhesion, translocation and immune evasion (Johnson et al., 1994). A multiplex PCR can be used for the detection of the presence of specific enterococcal virulence genes such as asa1, geE, cytA, esp and hly (Vankerckhoven et al., 2008). As an example, none of the 12 probiotic E. faecium strains tested by this multiplex PCR tested positive for the virulence genes. This multiplex PCR can be used for testing the intrinsic virulence capacity of a strain and, together with other molecular typing methods, it could be an additional criterion in assessing the safety of new potential probiotic E. faecium isolates (Vankerckhoven et al., 2008). Enterococcus faecalis carries a pathogenicity island (PAI) of 153 kb containing several virulence factors and is, therefore, believed to be more virulent than E. faecium, although horizontal transfer of the entire PAI into the chromosome of E. faecium has been demonstrated (Gomez et al., 2011; Vancanneyt et al., 2002). Enterococcus faecium is mostly used as probiotic like in four commercial tablet products in Japan, although they are mislabelled as containing E. faecalis (Hammad and Shimamoto, 2010).

Probiotic Bacillus strains are gaining increasing interest because their sporeforming capacity has obvious advantages in relation to stability and viability of the probiotic product when this contains spores instead of vegetative cells (Sanders et al., 2003). Moreover, it has become apparent in recent years that several Bacillus species, such as B. subtilis, have adapted to a life style in the gastrointestinal tract (Hong et al., 2009). The use of Bacillus spores as probiotic implies the direct consumption of high concentrations of viable cells. One of the commercial products produced in Europe and marketed in at least three EU countries (a.o. Belgium), namely Bactisubtil, seems to contain B. cereus spores, although the product label originally mentioned B. subtilis. The same strain as in Bactisubtil has also been used in the animal feed product Paciflor, which has been withdrawn in 2002 from production due to the ability of the strain to produce diarrhoea enterotoxins HBL (hemolytic enterotoxin complex) and NHE (nonhemolytic enterotoxin). Two other human probiotics produced outside Europe (Biosubtyl and Subtyl in Vietnam and Biovicerin in Brazil) also contain B. cereus spores. Strains belonging to the Bacillus cereus group are known to be able to cause two kinds of foodborne illness (SHC, 2009). First, there is an emetic (vomiting) illness due to the ingestion of food containing the heat-stable toxin cereulide. The second is a diarrheal infection due to the ingestion of Bacillus cereus strains producing heat-labile enterotoxins in the small intestine. Several published PCRs for these virulence genes or toxins could be used to screen B. cereus group strains (Wehrle et al., 2009). However, PCR detection of toxin genes is not a definite proof of potential toxin production, which should be looked for in a cytotoxicity test.

Probiotic products can also contain strains of, for example, B. licheniformis, B. clausii, B. subtilis and B. pumilus. Although much less important in food-poisoning incidents, strains of several of
these Bacillus species are also known to be potential producers of heat-stable or heat-labile toxins (e.g. De Jonghe et al., 2010). Because the B. cereus toxin PCRs are not valid for these toxins, a cytotoxicity test could be performed to exclude any pathogenic opportunity of the Bacillus strain (see references in De Jonghe et al., 2010).

E. coli Nissle strain 1917 is a well-known probiotic strain used in clinical trials to treat ulcerative colitis (e.g. Krusi et al., 2004). Yet, treatment with this strain has also been associated with sepsis such as a case of severe sepsis in a preterm infant (Guenther et al., 2010). Using a mice model, the safety of E. coli Nissle strain 1917 was assessed under different conditions of defective immunity and intestinal microbiota (Gronbach et al., 2010). It was found that if both the microbiota and adaptive immunity are defective, the strain may have potentially severe adverse effects. For other E. coli strains which would be considered as potential probiotics, it is important to ascertain that they don’t belong to one of the pathogenic E. coli groups, such as STEC, EHEC, ETEC, EIEC, EPEC, etc. (Nataro and Kaper, 1998). Several multiplex PCRs are described to investigate if an E. coli strain contains virulence genes and belongs to one of these pathogenic groups (e.g. Antikainen et al., 2009).

Propionibacteria and bifidobacteria belong both to the coryneform bacteria and are used in (probiotic) dairy products. The safety of these bacteria as dairy microorganisms has been recently reviewed (Meile et al., 2008). In contrast to the cutaneous Propionibacterium spp. or the so-called “acnes group”, the dairy Propionibacterium spp. are regarded as safe and do not carry any known virulence factor, although P. thoenii and P. jensenii strains show β-haemolytic activity. Bifidobacterium is certainly among the safest genera used as probiotics and the risks of healthy consumers being seriously infected by eating dairy products containing bifidobacteria is extremely low. Nevertheless, as bifidobacteria are common members of the human intestinal microbiota, they may behave as opportunistic pathogens like other commensal bacteria and indeed some commensal bifidobacteria have been connected with certain dental infections, pulmonary infections, bacteremia, abscesses and bloodstream infections. The non-probiotic B. dentium is the only bifidobacterial species classified as a pathogen.

Saccharomyces boullardii (present in Enterol®) has been associated with cases of fungemia (Enache-Angoulvant & Hennequin, 2005). Several factors constitute excessive and undue risk for development of Saccharomyces fungemia during probiotic administration. These factors are the patient's immunocompromised state during critical illness, the potential for live yeast spore contamination of healthcare workers' hands during preparation of the probiotic capsule or sachet for administration, and introduction of live yeast from contaminated hands (even after hand-washing) to catheter sites (Venugopalan et al., 2010).

Currently, probiotics or synbiotics are being used experimentally in patients hospitalized in intensive care units (ICU), so-called critically ill patients, because in these patients significant alterations in the gut microbiota occur which can lead to severe sepsis with associated multisystem organ dysfunction and death. It remains uncertain whether the use of probiotics or synbiotics in these circumstances is beneficial or even dangerous to the clinical outcome. There is a need for well designed multi-center studies with a defined mixture of bacteria on a defined group of critically ill patients before any conclusion can be drawn. In addition, the end-points have to be clearly defined (Jacobi et al., 2011). Recently, it has been concluded from a clinical trial of probiotic prophylaxis in predicted severe acute pancreatitis patients, that probiotic prophylaxis should not be administered in this category of patients because the probiotic preparation used (Ecologic® 641 consisting of six strains of viable and freeze-dried bacteria, namely Lactobacillus acidophilus, Lactobacillus casei, Lactobacillus salivarius, Lactococcus lactis, Bifidobacterium bifidum and Bifidobacterium lactis in a total daily dose of 10^10 bacteria) did not reduce the risk of infectious complications and was even associated with an increased risk of mortality (Besselink et al., 2008). Following the publication of this report, several reactions of colleagues appeared amongst which that probiotics should only be contemplated if the integrity of the gastrointestinal tract is not severely compromised (Bjarnason et al., 2008). In a recent comprehensive review on
probiotic infections in patients receiving probiotics in conjunction with nutritional support, it appeared that only 3 out of 53 trials, in which 4131 patients received probiotics, showed increased complications, which were largely non-infectious in nature and in specific patient groups (e.g. transplant and pancreatitis) (Whelan and Myers, 2010). The authors recommend preliminary safety trials when a probiotic is to be investigated for the first time in a patient group receiving nutritional support and that caution should be taken in patients with risk factors for adverse events.

Genome analysis of probiotic strains

With the advent of next generation sequencing techniques, the number of full bacterial genomes being sequenced has increased rapidly. In Table 3, > 50 complete genomes of probiotic strains of bifidobacterial and LAB strains are listed, and > 100 more genomes are being sequenced. Comparative genomics are now being used to find core genes, niche-specific genes and genes linked to specific probiotic traits, but can as well be used to find or exclude virulence or antibiotic resistance genes or to find indications of chromosomal integration of horizontally acquired DNA (e.g. sequence context screening of tRNA genes), which could indicate the potential of horizontal transfer of virulence or resistance genes. For example, from a comparative genomic analysis between a probiotic and a clinical E. faecalis strain, it seems that several of the above mentioned enterococcal virulence factors present are absent in the probiotic strain E. faecalis Symbioflor I (Domann et al., 2007). Likewise, a genomic comparison between the probiotic strain E. coli Nissle 1917 and other E. coli strains has indicated the lack of defined virulence factors (i.e. α-hemolysin, P-fimbrial adhesions) in the probiotic strain (Grozdanov et al., 2004), but another study indicated that genetic variations (e.g. mutations) and gene expression differences, rather than genomic content of virulence genes per se, contribute to the divergence in the pathogenic traits between E. coli strains (Vejborg et al., 2010).

Metabolic activity (enzymatic activity associated with production of toxic substances)

Another requisite of probiotics is that the probiotic bacteria should not produce harmful substances by metabolic activities. One way to test this is to assess whether the strain converts food components or biological secretions into secondary substances harmful to the host. For example, some intestinal bacteria are known to convert proteins and their digested products into ammonia, indol, phenols and biogenic amines (histamine, tyramine, putrescine, etc.) (Drasar, 1974). There are no real indications on the production of harmful compounds by Lactobacillus and Bifidobacterium species. However, Araya-Kojima and co-workers (1995, 1996) measured the enzyme activities related to the consumption and generation of ammonia in Bifidobacterium species of human origin. Compared with other bacteria of the intestinal microbiota, Bifidobacterium species have a lower deaminase activity involved in the production of ammonia from amino acids but a higher ammonia assimilation activity. Secondary bile acids are important harmful substances that are produced by intestinal bacterial actions on body secretions. They may exhibit carcinogenicity by acting on the mucous-secreting cells and promoting their proliferation, or they may act as promoters of carcinogenesis (Cheah, 1990). Many intestinal bacteria, including Bifidobacterium and Lactobacillus species, can deconjugate conjugated bile acids (Midtvedt & Norman, 1967). However, Bifidobacterium spp., Lactobacillus spp., Leuconostoc lactis subsp. lactis and S. thermophilus have been reported to lack the 7α-dehydroxylase activity that is related to the production of secondary bile acids (Takahashi et al., 1994; Ferrari et al., 1980). For Enterococcus, cytolytic substance and other virulence factors have been reported (Jett et al., 1994).

Platelet-aggregating activity and mucus degradation activity

Platelet aggregating activity has been considered to be a required test in the assessment of probiotic safety. Aggregation of platelets by bacteria is thought to contribute to the progression of infective endocarditis (Douglas et al., 1990). In this context, Harty and co-workers (1993a) measured the platelet-aggregating activity of strains of Lb. rhamnosus and Lb. paracasei subsp.
paracasei isolated from infective endocarditis, laboratory strains of the same species, and strains of the species Lb. acidophilus, Lb. fermentum, Lb. oris, Lb. plantarum, and Lb. salivarius. The platelet-aggregating activity was shown to be very strain-specific. The aggregation is thought to be associated with the proteins on the outer cell layer. The properties of the outer cell layer have been measured by hydrophobicity, hydroxyapatite adhesion and salivary aggregation. Lactobacillus rhamnosus strains isolated from infective endocarditis have higher activities than do laboratory strains of Lb. rhamnosus (Harty et al., 1993b). As for the other virulence factors, the activities of glycosidases and proteases (arylaminidase), which might enable the breakdown of human glycoproteins and the synthesis and lysis of human fibrin clots, have been measured in Lb. rhamnosus, Lb. paracasei subsp. paracasei and other strains. Some strains produce these enzymes, suggesting that they may have an infective property in causing endocarditis (Oakey et al., 1995). However, a study that aimed to measure the enzymatic activities relating to degradation of intestinal mucus glycoprotein in several strains of Lactobacillus and Bifidobacterium found no such activity in these strains (Ruseler-Van Embden et al., 1995). Further research on the structure of the outer cell layer or the above-mentioned enzyme activities in probiotic bacterial strains is expected. Whether the outer layer structure, which contains surface proteins, glycoproteins and lectins, is really related to infectivity and whether glycosidases, proteases (arylaminidase) and other enzymes capable of degrading human intestinal cells are related to infection remain to be elucidated.

3.5. **Safety parameters “under debate”: colonization, adhesion and translocation**

As mentioned above, the QPS list used in Europe describes the microorganisms that can be considered safe for use in food applications. Members on this list often have “a long history of safe use”, without any negative effect mentioned in the literature. The QPS list is based on identification at the **species level**, while it is generally accepted that probiotic effects are **strain-specific**. It is fair to say that also virulence factors are strain-specific and may vary largely within a species. As an example, *Escherichia coli* is often mentioned. This species comprises harmless commensal strains, which we all carry with us without any problem, but pathogenic strains which are, for instance, enteroinvasive (EIEC; [www.fda.gov/food/foodsafety/foodborneillness/foodborneillnessfoodbornePathogensNaturalToxins/BadBugBook/ucm071298.htm](http://www.fda.gov/food/foodsafety/foodborneillness/foodborneillnessfoodbornePathogensNaturalToxins/BadBugBook/ucm071298.htm)) or enterohaemorrhagic (EHEC; [www.fda.gov/food/foodsafety/foodborneillness/foodborneillnessfoodbornePathogensNaturalToxins/badbubgbook/ucm071284.htm](http://www.fda.gov/food/foodsafety/foodborneillness/foodborneillnessfoodbornePathogensNaturalToxins/badbubgbook/ucm071284.htm)) are widely known and studied. Underlying mechanisms for invasiveness and pathogenicity are gradually being understood, although many uncertainties remain.

In the process of infection and invasion, three aspects may be important: a first contact or adhesion between the bacterial strains and the epithelial cells, a further translocation of the strain into or through the intestinal epithelium and proliferation in the sterile body site, either at the level of the lamina propria, the mesenteric lymph nodes or systemically (Berg, 1992; Dietch et al., 1992), leading to sepsis, endocarditis and bacteremia (Steinberg 2003). For this reason, it has been suggested that the **adhesion** and **translocation** potential of a strain should be considered as part of the safety evaluation of probiotics (Salminen & Marteau, 1997).

**Adhesion** has been considered as a possible probiotic characteristic, since adhesion can prolong the intestinal colonization of the probiotic strain, improve the beneficial immune interactions, occupy receptors that could otherwise also “accommodate” pathogens and fortify the intestinal barrier. Clearly, the subject is controversial and further research into the many factors that may influence the outcome of adhesion tests is required. Different tests, different epithelial cell lines, whether or not mucus was included, or simply different laboratories all seem to result in different findings. In addition, also the physiological status of the bacteria seems to matter and, consequently, many doubts exist on the value of *in vitro* tests to predict the *in vivo* effect of a particular strain. Adhesion may also depend on the local competition with the commensal microbiota, on the number of bacteria consumed, and above all, eventual translocation will...
heavily depend on the immune status of the hosts. Effects of translocated bacteria may also be very different.

The way to deal with this is far from clear. The absence of pathogenicity and infectivity is a prerequisite of probiotic safety. The isolation of LAB or bifidobacteria from clinical cases, however, is likely to be the result of opportunistic infections (Adams & Marteau, 1995; Donohue & Salminen, 1996; Klein et al., 1992). To some extent, the increasing isolation rate from these infections may be due to an increased awareness of the role of these bacteria in opportunistic infections, or may result from the use of improved identification methods. A sensible approach in studying this would be to consider the question whether invasion of the host by the bacteria leads to infection and whether infection results in a severe outcome (Ishibashi & Yamazaki, 2001).

In this approach, translocation is probably a much more important phenomenon than adhesion, as adhesion without translocation is rarely a problem and could, as argued above, even be beneficial. Systemic infection by intestinal bacteria after translocation is a cause of opportunistic infection in immunocompromised hosts (Sedman et al., 1994; Wells et al., 1992) and may be linked to intestinal mucosal injury, immunodeficiency of the host or bacterial overgrowth (Ishibashi & Yamazaki, 2001; Berg et al., 1988; Deitch et al., 1985).

"Infective" bacterial translocation from the intestine is difficult to induce in healthy animals (Berg 1980; Daniel et al., 2006), although "controlled" bacterial translocation can be seen as a highly regulated, physiological event that occurs continuously in healthy subjects at a low rate (Daniel et al., 2006). When the integrity of the intestinal barrier is disturbed or when the immune system is not able to confine an infection, pathogenic or commensal bacteria can reach the bloodstream and cause septicemia (Berg, 1999). Therefore, antibiotic treatment, administration of immunosuppressive agents, or induction of colitis are used to measure bacterial translocation (Salminen & Marteau, 1997; Berg, 1983; Daniel et al., 2006). While bacterial translocation does not occur easily in healthy specific pathogen free (SPF) animals, it is known to occur for a long duration in germ-free mice (Ishibashi and Yamazaki, 2001; Berg and Garlington, 1979; Maejima and Tajima, 1973), linked to the immature intestinal barrier and the underdeveloped immune system of these germ-free animals (Deitch et al., 1991; Foo & Lee, 1972).

Assessment of the safety of probiotics from various angles is not a simple task (Ishibashi and Yamazaki, 2001). The test item that has been attracting attention is whether the bacteria possess infectivity. Assessment of the ability to cause opportunistic infection is difficult. The acute and chronic toxicity tests probably provide circumstantial evidence. However, observations of the passage of bacteria across the intestinal barrier and invasion of the host body by translocation provide more direct data for determining infectivity.
4. QUALITY CONTROL ON FINAL PRODUCTS

4.1. Microbial contamination of the final product

Probiotic foods have steadily gained popularity over the past decades and a wide variety of foods nowadays contain probiotic cultures. Strains are selected based on their specific health-promoting effects, but it is obvious that the safety aspects are also carefully considered to ensure that they do not pose any health risk for the consumer. The safety evaluation usually includes screening for (transferable) antibiotic resistance genes, virulence or pathogenic properties, undesirable metabolic activities and collecting of evidence to demonstrate a “history of safe use”, etc. (Salminen et al., 1998). Once a strain has been approved, it must still be determined whether the analytical methods that are normally used to verify the microbiological safety of the ingredients and the finished products can also be used for the product with the probiotic strains. For microbiological methods, this is not very obvious: finished products typically contain ca. 7 to 8 log cfu/g and the initial starter may contain more than 11 log cfu/g and it should be taken into account that the presence of undesirable contaminants is masked by the abundance of the beneficial microorganisms.

Theoretically, this problem is most likely to occur with non-selective cultural methods. However, even with selective methods this possibility should be considered, in particular because many of these methods include a non-selective pre-enrichment step. This is, for instance, the case for various internationally recognized protocols, for example for the isolation and detection of Salmonella (ISO standard 6579:2002).

A study performed by Joosten et al. (2006) clearly demonstrated that false-negative results could be obtained for the detection of Salmonella in infant powder with probiotics. The high incidence of false-negative results can probably be explained by the metabolic activities, properties of the probiotic bacteria, in particular the production of organic acids, whose accumulation could render the pre-enrichment broth into a hostile environment for Salmonella. By using double strength buffered peptone water (BPW) supplemented with vancomycin (10 μg/ml) and malachite green (100 μg/ml) and non-fat dry milk powder (10 g/l) as pre-enrichment medium, the recovery of Salmonella was much better (Joosten et al., 2006). For the detection of other pathogenic bacteria, especially when a non-selective enrichment is used, a similar problem could be observed. By adding antimicrobial compounds to selectively suppress the growth and/or metabolic activity of the probiotic bacteria this problem could be resolved. But more research is needed to optimise the enrichment procedures.

For the enumeration of the total microbiota, especially the contaminating microbiota (without the enumeration of the probiotic strain), the addition of 2 % sodium phosphate or 5 % glycerophosphate could solve the problem (Champagne et al., 2009). To study more in detail the problem of detection of contaminants in starter cultures and probiotics, a specific ISO working group started in 2010 (ISO/TC 34/SC9).

4.2. Microbial composition

Several research labs have independently analyzed the microbial composition of probiotic dairy products (Reuter, 1997; Masco et al., 2005; Holzapfel et al., 1998; Hamilton-Miller et al., 1999; Temmerman et al., 2003a,b). The overall conclusion from these studies is that a considerable number of dried food supplements and - although to a much lesser extent - dairy products are incorrectly or inadequately labeled, with regard to the correct identity of the incorporated probiotic strains. At a time when consumers become more and more aware of the important link between nutrition and health, it is thus of paramount importance that probiotic products with claimed health-promoting effects are well-controlled regarding their microbial composition.
Ideally, microbial analysis of probiotic products relies on standardized and accurate procedures for both the isolation and the identification of the implemented strains. In practice, however, microbial quality control of probiotic products is carried out using a culture-dependent or a culture-independent approach, or a combination of both, with each of these approaches having specific drawbacks and limitations. Especially in the case of multispecies products, a reliable taxonomic inventory may be difficult to achieve.

In a culture-dependent approach, the most crucial step is the recovery of the probiotic strain(s) from the product matrix, using one or more selective isolation media (Schillinger, 1999; Coeuret et al., 2004). Some probiotic strains are the result of isolation campaigns that employed very specific growth conditions which are not always provided by commercial media or by the standard set of incubation parameters used for isolation. In this context, it has been shown that especially *Bifidobacterium* strains may be hard to recover from the original products, and that selective isolation of bifidobacteria from products which also contain LAB is not always straightforward (Temmerman et al., 2003a; Masco et al., 2005). Although still far from optimal, improved protocols and selective media with a higher performance have been proposed for specific enumeration and isolation of bifidobacteria from (probiotic) samples (Roy, 2001; Masco et al., 2005).

After isolation, a limited number of colonies are usually subjected to taxonomic characterization for the purpose of species identification as described in Chapter 2. When the most optimal isolation conditions were applied but culture-dependent analyses are negative, it can be concluded that the targeted bacteria are either absent or are present in numbers beneath 1000 cfu/ml or cfu/g, which is generally considered to be the detection limit of culture-dependent analyses.

In order to circumvent the possible pitfalls of conventional culturing, culture-independent methods are increasingly being used for both qualitative and quantitative microbial analysis of probiotic products, because it may overcome some of the major disadvantages or limitations of culture-dependent approaches in terms of speed, taxonomic resolution and reproducibility. Denaturing gradient gel electrophoresis (DGGE) is a DNA fingerprinting technique that has been widely used to unravel the microbiological composition of commercial probiotic products (Ercolini, 2003; Temmerman et al., 2003b; Fasoli et al., 2003; Masco et al., 2005; Theunissen et al., 2005). Essentially, the DGGE method relies on (i) the isolation of total genomic DNA from the probiotic product, (ii) the selective amplification of a hypervariable region of the 16S rRNA gene by community PCR, and (iii) the electrophoretic separation of the resulting pool of PCR amplicons based on sequence content using DGGE (Huys et al., 2008). In theory, the resulting DGGE fingerprint will visualize all species present in a given probiotic product by a unique band, which can be identified by band position analysis, band sequencing and/or band hybridization. Despite the simplicity of its methodological concept, however, the interpretation of a DGGE fingerprint requires specific expertise, as some band positions may coincide with these of other phylogenetically closely related bacteria, some species may be represented by multiple bands due to the so-called 16S rDNA multi-operon effect, or species present in numbers beyond the detection level may not be visible (Huys et al., 2008). To improve the detection capacity of DGGE, group-specific primers can be be used (Huys et al., 2008).

Whereas DGGE has been successfully used to determine the microbiological composition of probiotic products, it does not provide a lot of information regarding the relative number of each species present. As discussed in Chapter 2, a range of validated 16S rRNA-targeted oligonucleotide probes is available for the identification of LAB ranging from group and genus to species and subspecies level (Ben Amor et al., 2007). Commonly, these probe sequences are converted to genus-, species- or strain-specific PCR primers in the design of real-time quantitative PCR assays to assess the relative concentration of the constituting strains and species in a given probiotic product (Vitali et al., 2003; Furet et al., 2004; Masco et al., 2007).
4.3. Microbial concentration and stability

The quality of a microbiological product, such as a starter or more generally a powder enriched with microbial cells, is generally quantified by its content in microbial cells, and among these cells two properties being expected: the ability to divide and to display a metabolic activity when introduced in a medium or a food composition. These properties are generally represented by a term called viability. However, recent studies have shown that cell division and metabolic activity are not always correlated, since microbial cells are able to reach a transient state where no cell division occurs but metabolic activity is maintained (Booth, 2002), leading to a distinction between viability (or ability to divide) and vitality (related to the metabolic activity). These observations have led to the distinction between three classes: viable and cultivable (VC), non-viable (NV) and viable but non cultivable (VBN C). This last class has been the subject of intensive studies followed by the development of a dedicated method in order to make the distinction between VC, NV and VBNC states (Lowder, 2000). Traditional microbiological methods rely on direct counting of microbial cells either by microscopy or by plate counting. The second method is generally preferred, since it gives directly the amount of cells able to divide with a result being expressed as “colony forming units”. However, this method presents several drawbacks: it is labor intensive, it is subjected to variability and it is not able to display the VBNC state. The emergence of fluorescence-based techniques has led to a great improvement of the understanding of microbial viability and its evolution throughout processes (Breeuwer, 2000). The use of specific fluorescent dyes allows to get a strong insight into the level of the intracellular structures in relation with cell viability. The most used techniques involve stains displaying different behaviors related to membrane permeability and/or degree of damage. The combination of fluorescent-based techniques with high-throughput experimental techniques has led to new opportunities in order to improve the analytical tools dedicated to the determination of the cellular properties (Müller, 2010). In this area, flow cytometry is an emerging technology in the field of food, environmental and industrial biotechnology for the assessment of microbial viability (Berney, 2007). The main advantage of this method is that it does not require a cultivation step of the microorganisms before analysis. Indeed, microorganisms present in the sample are separated and aligned cell by cell in an optical analysis chamber by a flow-focusing method. This way, optical properties can be acquired at the single cell level allowing to take into account the intrinsic heterogeneity of the microbial population (heterogeneity has been observed even in a clonal population). In addition to the above mentioned advantages, a flow cytometry-based method can be automated in order to follow cell properties on-line during a process. It can also be applied to follow product quality during storage after downstream processing steps, such as freeze drying and spray drying (Volkert, 2008).

4.4. Authenticity

The authenticity of a probiotic culture is an important criterion to ensure the expected quality and thus predicted health-promoting effect of the probiotic product. Linked to strain authenticity is genetic stability, which reflects the susceptibility of the culture concerning genomic rearrangements in the course of its natural evolution. These rearrangements may reflect small variations introduced at specific or random positions of the genome through point mutations, deletions and insertions, but may also be linked to larger structural variations resulting from homologous recombination (vertical inheritance) and horizontal gene transfer events. Although this is a highly relevant issue in order to ensure that specific health-promoting characteristics and functionalities are not affected during long-term preservation and production, few studies have reported comprehensive data documenting the genetic stability of commonly used probiotic strains. Ideally, a rigorous assessment of a strain’s genetic stability requires the availability of its whole-genome sequence. In the absence of this information, however, the use of molecular typing techniques probably provides the best estimate of genetic stability at the individual strain level.
A preliminary verification of bacterial strain authenticity can be obtained by partial 16S rRNA gene sequencing. If this analysis confirms the species identity of the probiotic culture, further characterization at strain level may be required. In Chapter 2, a series of typing methods is discussed which could be used for this purpose. However, as different typing methods offer different levels of genotypic resolution, the choice of the method and the appropriate protocol are crucial. As far as DNA fingerprinting approaches are concerned, AFLP analysis and PFGE of macrorestriction fragments offer the highest resolution at strain level (Chapter 2). These two methods are excellent tools for genotypic comparisons throughout the production or shelf-life period of a product. Sequence-based approaches such as the MLST schemes developed for several Lactobacillus and Bifidobacterium species are also relevant for typing of probiotic cultures, although their usefulness in strain authenticity matters still needs to be verified. Although not supported by producers and distributors of commercial probiotic products, deposit of probiotic cultures into an internationally recognized culture collection would provide an enduring source of reference material for confirmation of genetic stability.

Although it is generally assumed that Lactobacillus and Bifidobacterium strains used in probiotic applications show a high genotypic stability under different production conditions, more direct and in-depth evidence for this hypothesis is needed. Ideally, this should be done using a series of different molecular typing methods or, ultimately, comparative genomics. A number of genome projects have revealed that species used in probiotic products have specifically adapted themselves to specific environments. This is exemplified in the genomes of Bifidobacterium longum subsp. longum and Bf. longum subsp. infantis by the presence of many genes involved in the uptake and utilization of host-indigestible complex carbohydrates and polyols, supporting their genome adaptation to the human large intestine, where these are the predominant nutrient sources (Schell et al., 2002; Lee & O’Sullivan, 2010). The genome of Lactobacillus delbrueckii subsp. bulgaricus, which is applied worldwide in yogurt production, is in a phase of rapid reductive evolution, as a possible result of its adaptation from a plant-associated habitat to a milk environment through the loss of superfluous functions and protocooperation with S. thermophilus (van de Guchte et al., 2006). In the same way, comparative genomics could also determine the potential of probiotic strains to acquire and/or transfer DNA elements during host passage and long-term colonization, which is a research area that has remained virtually unexplored.

4.5. Labelling and claims

Official controls by national authorities are performed to ensure verification of compliance with food law. Apart from the risk of using unauthorized strains, product mislabelling is a known problem, partly because of the use of phenotyping or genotyping methods with a lack of discriminative power (Huys et al., 2006). In addition to official controls, private controls by food-producing companies are important in the frame of protection of patented strains and industrial property rights.

In their “Guidelines for the Evaluation of Probiotics in Food” document, the FAO/WHO working group (FAO/WHO, 2002) recommends that the following information should be described on the label of probiotic products:

- genus, species and strain designation. Strain designation (definition) should not mislead consumers about the functionality of the strain;
- minimum viable numbers of each probiotic strain at the end of the shelf-life;
- the suggested serving size must deliver the effective dose of probiotics related to the health claim;
- health claim(s);
- proper storage conditions;
- corporate contact details for consumer information.
In most countries, only general health claims are currently allowed on foods containing probiotics. The FAO/WHO working group (FAO,WHO, 2002) recommended that specific health claims on foods be allowed relating to the use of probiotics, where sufficient scientific evidence is available. Such specific health claims should be permitted on the label and promotional material. For example, a specific claim that states that a probiotic “reduces the incidence and severity of rotavirus diarrhea in infants” would be more informative to the consumer than a general claim that states “improves gut health”. It is recommended that it has to be the responsibility of the product manufacturer that an independent third party review by scientific experts in the field be conducted to establish that health claims are truthful and not misleading.

In line with the suggestions of the FAO/WHO working group (FAO/WHO, 2002), on December 20, 2006, the European Parliament and the Council published a novel regulation (Regulation (EC) N°1924/2006) on “Nutrition and Health Claims Made on Foods” (http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CELEX:32006R1924R%2801%29:EN:NOT). This regulation applies to all nutritional and health claims relating to all types of food intended for final consumers, thus also including probiotic products brought to the market with a health claim. The regulation aims to harmonise the nutrition and health claims at European level in order to better protect consumers, including commercial communications (labelling, presentation and promotional campaigns) and trade marks and other brand names which may be construed as nutrition or health claims. The regulation establishes the authorisation procedures required to ensure that claims on food labelling, presentation and advertising are clear, concise and based on evidence accepted by the whole scientific community.

The administration was represented by Isabel DE BOOSERE.

The working group was chaired by Nathalie DELZENNE and Georges DAUBE, the scientific secretary was Jean-Jacques DUBOIS.
About the Superior Health Council (SHC)

The Superior Health Council is a federal body that is part of the Federal Public Service Health, Food Chain Safety and Environment. It was founded in 1849 and provides scientific advisory reports on public health issues to the Ministers of Public Health and the Environment, their administration, and a few agencies. These advisory reports are drawn up on request or on the SHC's own initiative. The SHC takes no decisions on the policies to follow, nor does it implement them. It does, however, aim at giving guidance to political decision-makers on public health matters. It does this on the basis of the most recent scientific knowledge.

Apart from its 25-member internal secretariat, the Council draws upon a vast network of over 500 experts (university professors, members of scientific institutions), 200 of whom are appointed experts of the Council. These experts meet in multidisciplinary working groups in order to write the advisory reports.

As an official body, the Superior Health Council takes the view that it is of key importance to guarantee that the scientific advisory reports it issues are neutral and impartial. In order to do so, it has provided itself with a structure, rules and procedures with which these requirements can be met efficiently at each stage of the coming into being of the advisory reports. The key stages in the latter process are: 1) the preliminary analysis of the request, 2) the appointing of the experts within the working groups, 3) the implementation of the procedures for managing potential conflicts of interest (based on the declaration of interest, the analysis of possible conflicts of interest, and a referring committee) and 4) the final endorsement of the advisory reports by the Board (ultimate decision-making body). This coherent set of procedures aims at allowing the SHC to issue advisory reports based on the highest level of scientific expertise available whilst maintaining all possible impartiality.

The advisory reports drawn up by the working groups are submitted to the Board. Once they have been endorsed, they are sent to those who requested them as well as to the Minister of Public Health and are subsequently published on the SHC website (www.css-hgr.be), except as regards confidential advisory reports. Some of them are also communicated to the press and to target groups among healthcare professionals.

The SHC is also an active partner in developing the EuSANH network (European Science Advisory Network for Health), which aims at drawing up advisory reports at the European level.

In order to receive notification about the activities and publications of the SHC, you can send an e-mail to info.hgr-css@health.belgium.be.
